## Author Note

This research was funded by National Institutes of Health Grants AG048233 and MH55687. We thank Patrick Crutchley, Jonathan Miller, and Isaac Pedisich for assistance with programming the experiments and Adam Broitman, Elizabeth Crutchley, Kylie Hower, Joel Kuhn, and Logan O'Sullivan for help with data collection. We thank Jeremy Caplan and Marc Howard for helpful comments on the manuscript. Correspondence concerning this article should be addressed to M. Karl Healey (khealey@msu.edu) at Michigan State University or Michael J. Kahana (kahana@psych.upenn.edu) at University of Pennsylvania.

## CONTIGUITY IN EPISODIC MEMORY

2

## Abstract

Contiguity is one of the major predictors of recall dynamics in human episodic memory. But there are many competing theories of how the memory system gives rise to contiguity. Here we provide a set of benchmark findings for which any such theory should account. These benchmarks are drawn from a review of the existing literature as well as analyses of both new and archival data. They include 34 distinct findings on how various factors including individual and group differences, task parameters, and type of stimuli influence the magnitude of the contiguity effect. We will see that contiguity is observed in a range of tasks including recognition, paired associates, and autobiographical recall and across a range of time scales including minutes, days, weeks, and years. The broad pattern of data point toward a theory in which contiguity arises from fundamental memory mechanisms that encode and search an approximately time scale invariant representation of temporal distance.

*Keywords:* episodic memory; free recall; recognition; paired associates; temporal contiguity

### Contiguity in Episodic Memory

Recall of one event often evokes memories of other events that occurred nearby in time. In the laboratory, this *temporal contiguity effect* is observed when subjects study and then recall lists of words: the order in which they recall the words tends to be similar to the original presentation order (for early reviews, see Postman, 1971, 1972). Here we provide an overview of what we currently know about the contiguity effect by presenting 34 findings concerning how the effect is influenced by various factors and manipulations. Some of these come from a review of previous work, others are novel findings from the Penn Electrophysiology of Encoding and Retrieval Study (PEERS Healey & Kahana, 2014; Lohnas & Kahana, 2014; Miller, Kahana, & Weidemann, 2012, ; see Appendix A for methods). Our overview is divided into seven sections: basic properties of the contiguity effect in free recall, individual and group differences, manipulations of task parameters, manipulations of stimuli, manipulations of encoding tasks, contiguity in other memory tasks, and contiguity at long time scales. Table 1 lists the 34 findings we will discuss and their original reference. We conclude with an evaluation of the ability of six different memory mechanisms to account for the findings: associative chaining, short-term memory, positional coding, chunking, contextual dynamics, and control processes.

#### Basic properties of the contiguity effect in free recall

**Finding 1: Temporal Contiguity in free recall.** Kahana (1996) quantified the contiguity effect in immediate free recall by computing the probability of successively recalling items as a function of their distance from each other in the study list. After recalling an item studied in position  $i$  of the list, one can measure the probability of transitioning to next recall an item studied in position  $i + lag$ , conditional on the availability of that item for recall. This measure is called the lag *conditional-response probability* (lag-CRP). When the list is sufficiently long to allow for transitions at long lags, the lag-CRP decreases monotonically with  $|lag|$  (Figure 1A plots the lag-CRP to  $|lag| = 10$  for 24-item lists). For shorter lists, long-lag transitions tend to involve transitions to

## CONTIGUITY IN EPISODIC MEMORY

4

1  
2  
3  
4 primacy or recency items, which can introduce a non-monotonicity in the lag-CRP (Farrell  
5 & Lewandowsky, 2008; Howard, Sederberg, & Kahana, 2009). Contiguity also manifests as  
6 faster inter-response times for absolute values of lag (Figure 1B).<sup>1</sup>  
7  
8

9  
10 **Finding 2: Forward asymmetry.** The contiguity effect is asymmetrical  
11 (Figure 1A), such that forward transitions are more likely than backward transitions for  
12 small absolute values of lag (Kahana, 1996). The asymmetry effect has been shown in  
13 immediate free recall (where recall begins immediately after the last item is presented;  
14 Kahana, 1996), as well as in delayed (where a distraction filled interval introduces a delay  
15 between the last item and recall) and continual distractor free recall (where a distractor  
16 filled delay occurs after every item; Howard & Kahana, 1999). As we will discuss below,  
17 some theories naturally predict this asymmetry, others do not.  
18  
19  
20  
21  
22  
23  
24  
25

26 **Finding 3: Higher for early and late output positions.** One of the first  
27 factors shown to influence the size of the contiguity effect was position in the output  
28 sequence (Kahana, 1996). As shown in Figure 2A, in delayed free recall the contiguity  
29 effect is large for the first pair of items output and then drops, but remains robust, for  
30 intermediate output positions before rebounding for later outputs (for discussions of the  
31 sources of this effect see Farrell & Lewandowsky, 2008; Howard et al., 2009; Kahana, 1996).  
32  
33  
34  
35  
36  
37

38 **Finding 4: Consistent across serial positions.** We can also examine contiguity  
39 as a function of serial position at study. Figure 2B shows lag-CRPs in delayed free recall  
40 for transitions between items  $i$  and  $j$  separately for cases where item  $i$  was from early, mid,  
41 and late serial positions. A clear contiguity effect is present across input positions. For  
42 early serial positions, the negative-lag conditional response probabilities are elevated,  
43  
44  
45  
46  
47

48  
49 <sup>1</sup>For a given lag, the *conditional-response probability* is computed by dividing the number of times a  
50 transition of that lag was *actually* made by the number of times it *could* have been made (Kahana, 1996).  
51 When determining the number of times a transition of a given lag could have been made, transitions that  
52 would lead outside the list boundaries are excluded (e.g., a +2 lag is impossible after recalling the 15<sup>th</sup>  
53 item in a 16-item list), as are transitions to already-recalled items. The contiguity effect tends to be larger  
54 for the first few items recalled than for later output positions due to the strong recency effect, especially  
55 in immediate free recall (Farrell & Lewandowsky, 2008; Howard et al., 2009) Therefore, in the remaining  
56 analyses we focus on  $|lag| \leq 5$ , and unless we are specifically investigating the influence of output position,  
57 we exclude the first two outputs from the lag-CRP analyses in this paper.  
58  
59  
60

1  
2  
3  
4 consistent with Murdock's (1974) observation that after recalling several items from late  
5 serial positions, subjects tend to jump back to early serial positions.  
6  
7

8       **Finding 5: Compound cuing in free recall.** Reanalyzing data from several  
9 previous studies (including both immediate and delayed free recall), Lohnas and Kahana  
10 (2014) found that the contiguity effect was larger when the previous transition had been to  
11 an adjacent item ( $lag = +1$ ) than when it had been to a remote item ( $|lag| > 3$ ),  
12 suggesting that the retrieval cue for a given item includes information from multiple prior  
13 recalls—a compound cue.  
14  
15  
16  
17  
18  
19

20       **Finding 6: Contiguity is not due to fluctuations in efficiency of encoding.**  
21 The efficiency of encoding varies from moment to moment (Hintzman & Hartry, 1990;  
22 Kahana, Rizzuto, & Schneider, 2005; Sadeh, Moran, & Goshen-Gottstein, 2015). This  
23 variation could, in principle, produce an artificial contiguity effect (for a related point, see  
24 Hintzman, 2016). To see how, imagine a subject whose encoding efficiency starts high and  
25 fades over the course of a list. Consider what would happen if, every time they studied a  
26 list, they always successfully encoded the first two items but later items were each encoded  
27 only 10% of the time. In other words, imagine a subject with a very pronounced primacy  
28 effect. Assume this subject always begins recall by outputting the item from serial position  
29 1. From there, it would always be possible to transition to serial position 2. But only 10%  
30 of the time would it be possible to transition to serial position 3, or 4, or any later position.  
31 That is, making a lag of +1 would always be a possibility, but any given lag  $> 1$  would be  
32 possible only 10% of the time. Thus, even if this subject completely ignored lag when  
33 making transitions and instead randomly selected a successfully encoded item, they would  
34 still show a bias toward lag +1 transitions—an artificial contiguity effect. This artificial  
35 effect is not limited to our example of extreme primacy. It will arise whenever fluctuations  
36 in efficiency of encoding are autocorrelated across serial positions.

50  
51  
52  
53

54       To further illustrate, we created simulated data in which the contiguity effect *is* an  
55 artifact of fluctuations in efficiency of encoding. We started with an idealized serial  
56  
57  
58  
59  
60

1  
2  
3  
4 position curve that has two “pockets” of well-encoded items separated by many poorly  
5 encoded items (see the inset in Figure 3A), simulating autocorrelated changes in encoding  
6 efficiency. We then used this curve to define a binomial distribution of recall success for  
7 each serial position. Then, for each of 100,000 simulated lists, we predetermined which  
8 serial positions would be successfully recalled by randomly drawing from the distribution of  
9 each serial position. The model then output these recalled words in random order (i.e.,  
10 input order does not directly influence output order). The black line in Figure 3A shows  
11 that these simulated data do indeed exhibit an artifactual contiguity effect when the  
12 lag-CRP is computed in the standard way (though the effect is smaller and more linear  
13 than in real data).

16  
17  
18  
19  
20  
21  
22

23  
24 It is possible, however, to eliminate the influence of fluctuations in encoding success  
25 by recomputing the lag-CRP conditional on recall of both item  $i$  and item  $j$ . That is, we  
26 can equate rate of successful encoding across lags by considering a transition of a given lag  
27 possible only if both items involved in that candidate transition were actually successfully  
28 recalled at some point in the recall sequence. The gray line in Figure 3A shows that this  
29 adjustment completely eliminates the artifactual contiguity effect—when considering only  
30 items that are successfully recalled, the lag-CRP from the simulated data is flat. Is the  
31 contiguity effect in *real* data an artifact? Panels B and C of Figure 3 show that it is  
32 not—even when the lag-CRP is conditionalized on recall of both item  $i$  and item  $j$ , a  
33 strong contiguity effect remains. In the Supplemental Materials we apply this adjustment  
34 to all of the lag-CRPs presented in the main text—in no case does it eliminate the  
35 contiguity effect. That is, variation in encoding cannot account for the contiguity effect.

### 50 Individual and group differences

51  
52 Most work on the contiguity effect has reported data averaged across individuals.  
53 But recent work considering individual differences and differences between subgroups has  
54 revealed several important findings.  
55  
56  
57  
58  
59  
60

1  
2  
3  
4       **Finding 7: Consistency Across Individuals.** Healey and Kahana (2014) tested  
5 126 young adults in the immediate free recall task and found that, depending on how  
6 contiguity was measured, 96%–100% of individuals showed a contiguity effect. To illustrate  
7 this across-subject consistency here, we computed *temporal factor scores* (Polyn, Norman,  
8 & Kahana, 2009) for each younger and older adult in Experiment 1 of PEERS. The  
9 temporal factor score for a given transition is the percentile rank of the actual lag of the  
10 transition with respect to the lags of all transitions that were possible at that time,  
11 averaging these percentiles across all of a subject's transitions gives their overall factor  
12 score. Computing this score for each subject provides an across-subject distribution of the  
13 size of the temporal contiguity effect. Figure 2C shows the average lag-CRP for subjects in  
14 the top half of the distribution and compares it with the lag-CRP of the 5 subjects with  
15 the lowest temporal factor scores. Even the subjects with the lowest temporal factor scores  
16 show a clear contiguity effect.

17  
18  
19       **Finding 8: Changes Across the Lifespan.** The magnitude of the contiguity  
20 effect varies across the lifespan, increasing in childhood (Lehman & Hasselhorn, 2012;  
21 Lehmann & Hasselhorn, 2010; but see Jarrold et al., 2015) and decreasing in old age  
22 (Healey & Kahana, 2016; Kahana, Howard, Zaromb, & Wingfield, 2002; Wahlheim, Ball, &  
23 Richmond, 2017; Wahlheim & Huff, 2015)—though even those with the lowest levels of  
24 contiguity still show a clear effect. Figure 2D shows lag-CRPs for younger (18–30 years)  
25 and older adults (61–85 years) in PEERS Experiment 1 (immediate free recall).

26  
27  
28       **Finding 9: Personality and clinical variables.** Several studies have found that  
29 personality variables and clinical conditions correlate with changes in temporal contiguity  
30 in delayed free recall. Polyn et al. (2015) found that schizophrenic patients exhibited  
31 reduced temporal contiguity relative to a control group. Sahakyan and Kwapil (2018)  
32 found a reduction in contiguity relative to control among patients with negative schizotypy,  
33 but not among those with positive schizotypy. Murty et al. (2018) found a similar  
34 reduction in contiguity among a group of patients suffering their first episode of psychosis.

## CONTIGUITY IN EPISODIC MEMORY

8

1  
2  
3 Pajkossy, Keresztes, and Racsomány (2017) found that a bias for short lag transitions was  
4 positively correlated with trait worry but negatively correlated with trait anxiety. Finally,  
5 Gibson, Healey, and Gondoli (in press) have found that temporal contiguity is increased in  
6 individuals with ADHD relative to controls even though overall recall is decreased. These  
7 early studies suggest that temporal contiguity may provide a more sensitive measure than  
8 traditional neuropsychological tests that focus mainly on recall accuracy.  
9  
10  
11  
12  
13  
14  
15

16 **Finding 10: Increases with task experience.** In addition to changing across  
17 the lifespan, the magnitude of the contiguity effect changes as a subject gains experience  
18 with the free recall task. To examine contiguity at the naïve end of the practice spectrum,  
19 we looked at data from the initial screening session of PEERS in which subjects studied 12  
20 lists of 16 items for immediate free recall. Figure 2E shows the lag-CRP for subjects' 1<sup>st</sup>  
21 free recall list versus their 12<sup>th</sup> list. A clear contiguity effect is seen on the 1<sup>st</sup> list, but it  
22 grows larger by the 12<sup>th</sup> list (see also, Healey, 2018).  
23  
24  
25  
26  
27  
28  
29

30 To examine how contiguity evolves as subjects gain expertise in the task, we consider  
31 data from PEERS Experiment 4. In this experiment, a group of subjects who were initially  
32 naïve to the free recall task completed 24 sessions of delayed free recall after the initial  
33 screening session. In each session, subjects studied 24 lists of 24 items for delayed recall (cf.  
34 Experiment 1 which used immediate recall; as we discuss below, test delay has only a small  
35 effect on contiguity). Figure 2F shows that a large contiguity effect is present in the 1<sup>st</sup>  
36 session but grows even larger by the 24<sup>th</sup>.  
37  
38  
39  
40  
41  
42  
43

44 **Finding 11: Positive correlation with memory ability.** The fact that a  
45 qualitatively similar contiguity effect is consistently observed across individuals and age  
46 groups should not be taken to mean that quantitative variation in magnitude of the effect  
47 is unimportant. Indeed, subjects who show the most contiguity also recall the most words  
48 (Healey, Crutchley, & Kahana, 2014; Sederberg, Miller, Howard, & Kahana, 2010; Spillers  
49 & Unsworth, 2011). Figure 4 shows the correlation between contiguity (measured by  
50 temporal factor scores) and overall immediate recall accuracy in PEERS Experiments 1–3.

## CONTIGUITY IN EPISODIC MEMORY

10

1  
2  
3 examined lag-CRPs in immediate free recall at ten different list lengths between 2 and 15,  
4 and found a contiguity effect at all lengths. Figure 2J compares lists of 20 versus 40 items  
5 in the Murdock (1962) dataset. Although both lengths show a clear contiguity effect, the  
6 effect is larger for the shorter lists.  
7  
8  
9  
10

11  
12 **Finding 16: Robust to very fast presentation rates.** Presentation rate might  
13 strongly influence how items are encoded simply because longer presentation rates  
14 presumably give subjects more time to engage whatever processes produce contiguity.  
15 Figure 2K shows a robust contiguity effect in immediate free recall for presentation rates of  
16 0.5 seconds and 1 second. Howard (2017) examined very fast presentation rates and found  
17 a robust contiguity effect at rates as fast as 4 words per second. At 8 words per second,  
18 they found the lag-CRP began to flatten, perhaps due to an attentional blink-like effect.  
19  
20  
21  
22  
23  
24  
25

26  
27 **Finding 17: Robust to very slow presentation rates.** At the other extreme,  
28 Nguyen and McDaniel (2015, Experiment 3) examined lag-CRPs in delayed free recall when  
29 subjects were allowed to self pace their study of line drawings of familiar objects. Subjects  
30 studied each picture for an average of over 6 seconds but still showed a robust contiguity  
31 effect. Overall, then, the contiguity effect seems relatively insensitive to presentation rate.  
32  
33  
34  
35  
36

37  
38 **Finding 18: Approximate time-scale invariance.** In immediate free recall,  
39 items are presented with a short inter-item delay and subjects are asked to recall the words  
40 immediately after the presentation of the final list item. Delayed free recall adds a  
41 retention interval by asking subjects to engage in a distractor task for a period of time  
42 after the final item but before recall. Continual distractor free recall (CDFR) too, has a  
43 delay after the final item but also introduces a distractor-filled delay between each item  
44 during presentation (Bjork & Whitten, 1974). Figure 2L shows that all three versions of  
45 the task produce a clear contiguity effect (Bhatarah, Ward, & Tan, 2006; Howard &  
46 Kahana, 1999), with a slightly lower CRP at  $lag + 1$  for CDFR (cf. Howard, 2004). That  
47 is, contiguity is relatively invariant to changes in time scale (see below for discussion of  
48 timescales on the order of days and years)

### Manipulation of stimuli

We have seen that the details of how stimuli are presented (modality, rate, etc.) can modulate the size of the contiguity effect (though, like individual differences, not eliminate it). But most of these studies have randomly drawn stimuli from pools of common words. How does varying the nature of the stimuli impact contiguity?

**Finding 19: Reduced in orthographically distinct lists.** Ward, Woodward, Stevens, and Stinson (2003) examined the effects of word frequency on immediate free recall. They found a strong contiguity effect for both high and low frequency words in both mixed and pure lists. Similarly, in a delayed free recall task, McDaniel, Cahill, Bugg, and Meadow (2011) had subjects study lists that included orthographically distinctive items (i.e., words with unusual letter combinations such as *lynx*, *methyl*, *knoll*, *calypso*) and orthographically common items. The lists were either pure (all either distinctive or common) or mixed. They found substantial contiguity effects in mixed lists and pure common lists but found *no* contiguity effect in pure distinct lists. These results suggest that orthographically distinct words may disrupt the mechanisms that generally produce contiguity. Indeed this is the only study we are aware of that fails to find contiguity in the free recall of deliberately encoded items. Bean et al. (2017) recently replicated the relevant conditions from McDaniel et al. (2011) with a sample of 338 subjects (cf. 36 in McDaniel et al., 2011). They replicated the finding that orthographic distinctiveness substantially reduces the contiguity effect. Their larger sample size, however, revealed a significant effect even for pure distinctive lists. That is, orthographic distinctiveness reduces, but does not eliminate, the contiguity effect.

**Finding 20: Interacts with emotional valance.** Another aspect of meaning that influences recall order is the emotional content of stimuli (Long, Danoff, & Kahana, 2015; Siddiqui & Unsworth, 2011). Siddiqui and Unsworth (2011, , Experiment 1) gave subjects delayed free recall lists that were composed of eight positively valanced words, eight negatively valanced words, and eight neutral words, presented in random order.

Subjects showed a modest temporal clustering effect, even though the emotional context provided the opportunity to cluster recalls based on valence. In a second experiment, the researchers made the emotional content of the items more salient by asking subjects to rate the pleasantness of each item during study. This manipulation further reduced the level of temporal contiguity, without eliminating it entirely.

**Finding 21: Present when items vary in assigned value.** There is considerable evidence that the perceived importance of information influences memory performance (e.g., Castel, 2005; May, Rahhal, Berry, & Leighton, 2005). Even assigning arbitrary value to items can influence how information is remembered (Castel, Benjamin, Craik, & Watkins, 2002). Stefanidi, Ellis, and Brewer (2018) examined the influence of such value assignments on contiguity. In 10-item delayed free recall lists, they assigned each item a value between 1 and 10 and told subjects that the items with the highest values were the most important to remember. In one condition, values were randomly assigned to serial positions, in another condition, values were assigned to serial position in ascending order (i.e., the value of serial position 1 = 1, value of serial position 2 = 2, etc.), and in another, they assigned values in decreasing order of serial positions (i.e., the value of serial position 1 = 10, value of serial position 2 = 9, etc.). One could reasonably expect that these conditions would strongly influence both the encoding and search strategies subjects engage in (e.g., trying to recall the highest value items first). Indeed, recall probability increased as a function of value in all conditions. Yet, they found a typical forward asymmetric lag-CRP in all conditions, and the degree of contiguity did not differ substantially from a control condition in which subjects were told to ignore the numbers presented along with each item rather than being told they represented the value of the items. They did find however, that presenting items in order of value (either ascending or descending) substantially increased the temporal contiguity effect—assigned value and temporal proximity had additive effects.

1  
2  
3  
4       **Finding 22: Robust to variation in stimuli complexity.** Most of the studies  
5 we have reviewed used words as stimuli. In terms of perceptual complexity, words are quite  
6 impoverished compared to the things we usually want to remember outside the laboratory  
7 (e.g., complex visual scenes). Although contiguity was not their main focus, Nguyen and  
8 McDaniel (2015) suggested that memory for pictures might show a reduced contiguity  
9 effect due to less reliance on contextual details. Their stimuli were line drawings that were  
10 either complex (e.g., a drawing of a car including details like door handles and headlights)  
11 or simple (e.g., an outline of a car with no details). Stimuli were assigned to either pure  
12 lists of complex pictures, pure lists of simple pictures, or mixed lists. They found a clear  
13 contiguity effect with a forward asymmetry in all conditions with no significant differences  
14 between list conditions. Perhaps, because the pictures are nameable, subjects translated  
15 them into verbal codes. Cortis Mack et al. (2015) examined contiguity under a variety of  
16 conditions designed to reduce reliance on verbal codes (e.g., remembering locations of  
17 tactile stimulation of the face). They too found clear contiguity effects with all stimulus  
18 types. As we will see below, temporal contiguity has also been demonstrated in recall of  
19 complex memories formed outside the lab such as autobiographical events (Moreton &  
20 Ward, 2010) and news stories (Uitvlugt & Healey, in press).

38       **Finding 23: Dual-modality lists.** In the previous section, type of stimuli varied  
39 from list to list. Cortis Mack, Dent, and Ward (2018) varied it within a single immediate  
40 free recall list. At each serial position of the list, a word was presented over headphones  
41 and a spatial location was simultaneously presented as a dot on a computer screen.  
42 subjects were then asked to freely recall both the words (by saying them aloud) and dots  
43 (by clicking on the screen) in any order they wanted. Recall transitions could be either be  
44 within-modality (e.g., recalling two words in succession) or between modality (recalling a  
45 word then recalling a dot). Because words and dots were presented simultaneously,  $lag = 0$   
46 transitions were possible (e.g., recalling a dot and next recalling the word that was  
47 presented at the same time). These  $lag = 0$  transitions were the most frequent type—even

## CONTIGUITY IN EPISODIC MEMORY

14

1  
2  
3 when subjects could cluster by stimulus type, temporal proximity guided memory search.  
4  
5 In two additional experiments they pretested lists that alternated between words and dots  
6  
7 (rather than presenting two stimuli simultaneously) and again found a strong preference for  
8  
9 temporally proximate transitions at the expense of within-modality transitions.  
10

11  
12 **Finding 24: Categorized lists.** The presence of strong semantic associations  
13  
14 among list items could mitigate the need to rely on temporal associations to guide recalls.  
15  
16 Yet, the contiguity effect is seen even when every item is drawn for the same semantic  
17  
18 category (Miller, Lazarus, Polyn, & Kahana, 2013), which should provide very strong  
19  
20 semantic cues. McCluey, Burke, and Polyn (2018) directly assessed the influence of such  
21  
22 strong cues by having subjects study lists in which each item was drawn from the same  
23  
24 category or each item was drawn from a different category. As shown in Figure 2M,  
25  
26 although contiguity was modestly reduced in the same-category lists, it was still substantial  
27  
28 and robust (see also Kintsch, 1970). Polyn, Erlichman, and Kahana (2011) found that  
29  
30 when immediate free recall lists were composed of 8 items drawn from each of three  
31  
32 categories presented in a random order, contiguity actually emerged at two different levels:  
33  
34 when subjects transitioned between items from the same category they preferred category  
35  
36 members that were presented nearby in time and when they transitioned from one category  
37  
38 to another, they preferred categories that were presented nearby in time. That is, even  
39  
40 when subjects have strong semantic associations to rely on, temporal associations still  
41  
42 powerfully influence recall order.  
43

44  
45 **Finding 25: Temporal/semantic competition.** Even when a list does not  
46  
47 contain a clear category structure, more subtle semantics among items matter (Bousfield,  
48  
49 Sedgewick, & Cohen, 1954; Howard & Kahana, 2002b). Sometimes temporal and semantic  
50  
51 associations will tend to guide memory search in the same direction, as when a close  
52  
53 semantic associate of the just-recalled word was studied in an adjacent serial position.  
54  
55 Other times, the two types of associations can compete, as when a strong semantic  
56  
57 associate of the just-recalled item was studied in a remote serial position. The PEERS  
58  
59  
60

dataset allows us to assess contiguity in these two situations (for a similar analysis focusing on semantic contiguity see Howard & Kahana, 2002b). Each list in PEERS was constructed such that it had two pairs of high-similarity words with the members of one pair being presented in adjacent serial positions and the members of the other pair being separated by at least two other items (see Appendix A for details on list design). We examined recall transitions from items in cases in which a high-similarity associate of the item was available at a near lag ( $\leq 2$ ). In this case, temporal and semantic information complement each other. We also examined transitions from items in cases in which a high-similarity associate of the item was available only at a remote lag ( $> 5$ ). Here, temporal and semantic information compete with each other. As a control, we examined transitions from items in cases in which no strong associate of the item was available at any lag. As seen in Figure 2N, the presence of a strong associate modulated the lag-CRP in a systematic way, making it steeper when the associate was available at a near lag and making it shallower when the associate was available at a distant lag.

### Encoding Manipulations

So far we have considered cases in which subjects are told to study items for a memory test, but are given no specific instructions on how to study them. How is contiguity influenced by the nature of the processing subjects engage in during encoding?

**Finding 26: Encoding task manipulations.** In PEERS, subjects were asked to carry out a processing task for all items in some lists (a size or an animacy judgment) whereas on other lists, they were given no specific encoding task. As seen in Figure 2O, although a clear contiguity effect emerges in both conditions, it is modestly smaller when subjects are given a specific task (Long & Kahana, 2017). One limitation of this finding is that because encoding task was manipulated within-subject, subjects could have adopted a contiguity-generating strategy across all lists, regardless of assigned processing task—the reduction of contiguity might be even larger in a between-subjects design. Overall, the

## CONTIGUITY IN EPISODIC MEMORY

16

1  
2  
3 data suggest that imposing an arbitrary encoding task disrupts the processes that generate  
4  
5 contiguity.  
6  
7

8       **Finding 27: Mnemonic strategies.** Do all processing tasks reduce contiguity,  
9  
10 even those that are not arbitrary but are instead intended to improve memory? Bouffard,  
11  
12 Stokes, Kramer, and Ekstrom (2018) used delayed free recall to test the effect of such  
13  
14 mnemonic strategies by comparing lag-CRPs when subjects were given no encoding  
15  
16 strategy with lag-CRPs when subjects were given either the method of Loci, a similar  
17  
18 method that involved associating items to points on an autobiographical time-line rather  
19  
20 than spatial locations, or a method involving linking items to steps of a well-known  
21  
22 sequence (making a sandwich). All of these methods increased at least one measure of  
23  
24 temporal contiguity: The method of loci increased contiguity in both the initial delayed  
25  
26 recall and a final free recall test (i.e., recall items from any list presented in the  
27  
28 experiment), whereas the autobiographic and sequence method increased contiguity only in  
29  
30 final free recall.  
31

32       **Finding 28: Incidental encoding.** Almost all of the tasks we have considered  
33  
34 thus far explicitly asked subjects to memorize a list of stimuli and therefore encourage  
35  
36 processing that facilitates encoding. Does temporal contiguity emerge when encoding is  
37  
38 incidental and there is no incentive to attend to, let alone encode, the temporal distance  
39  
40 between events? Data from a variety of studies in which incidental encoding is followed by  
41  
42 order reconstruction tasks suggest that subjects do encode information about temporal  
43  
44 contiguity even when they are not deliberately studying (Glenberg and Bradley 1979;  
45  
46 Nairne 1991; Nairne, Cogdill, and Lehman 2017; for a review see Healey 2018). But the  
47  
48 fact that people have access to temporal information does not necessarily mean they will  
49  
50 use it to guide a free memory search after incidental encoding. We are aware of only two  
51  
52 studies that have directly tested for temporal contiguity after incidental encoding using  
53  
54 modern measures (Burns, 1996, did report a measure of the number of  $|lag| = 1$   
55  
56 transitions, but did not test if they were more frequent than other lags).  
57  
58  
59

## CONTIGUITY IN EPISODIC MEMORY

17

1  
2  
3  
4 Nairne et al. (2017) reported a series of experiments investigating the survival  
5 processing effect (Nairne & Pandeirada, in press; Nairne, Thompson, & Pandeirada, 2007).  
6 In the first experiment, subjects completed a survival processing task that made no  
7 mention of memorizing the items: they viewed a list of items and for each rated its  
8 relevance to a survival (or control) scenario. But there was a surprise delayed free recall  
9 test approximately two minutes after the end of the list. Temporal clustering was not  
10 significantly above chance as assessed by the temporal factor score even though subjects  
11 recalled a substantial number of items (approximately 45% accuracy across conditions). A  
12 second experiment used a different processing task as a control to the survival processing  
13 task. Again, there was no evidence of temporal contiguity—even though recall levels were  
14 high.  
15

17  
18  
19  
20  
21  
22  
23  
24  
25

26 Healey (2018) followed up on these findings by presenting over 2000 subjects with a  
27 surprise delayed free recall test after various incidental encoding tasks. The results show  
28 that incidental encoding substantially reduces the temporal contiguity effect. But it does  
29 not eliminate it: The average effect size across the different incidental encoding tasks was  
30 small (Cohen's  $d$  was approximately 0.13) but reliably greater than zero.  
31  
32  
33  
34  
35

36 Taken together, the evidence from incidental encoding studies suggests that the  
37 temporal contiguity effect occurs automatically, but is powerfully amplified by the intent to  
38 encode. The finding that incidental encoding dramatically reduces contiguity without  
39 substantially reducing recall levels is problematic for models that posit a tight coupling  
40 between recall and contiguity (for a discussion see Healey, 2018).  
41  
42  
43  
44  
45

46 The studies reviewed in this section highlight the importance of how items are  
47 processed at encoding. Some types of processing result in less temporal information being  
48 encoded. Although much more work needs to be done, the current evidence suggests that  
49 manipulations that encourage item-specific processing over relational processing tend to  
50 produce smaller contiguity effects (Bouffard et al., 2018; McDaniel et al., 2011; Nguyen &  
51 McDaniel, 2015).

### Contiguity in other tasks

**Finding 29: Contiguity in serial recall errors.** As has been repeatedly demonstrated, serial recall relies on many of the same mechanisms as free recall (Bhatarah et al., 2006; Spurgeon, Ward, & Matthews, 2014; Spurgeon, Ward, Matthews, & Farrell, 2015; Ward, Tan, & Grenfell-Essam, 2010). Thus there may be similar contiguity effects in the two tasks. Indeed, both some early data (Lee & Estes, 1977) and recent analyses using lag-CRP methodology show that although there is a strong forward bias, serial recall exhibits a contiguity effect (Solway, Murdock, & Kahana, 2012; Spurgeon et al., 2015) that extends over multiple lags in both the forward and backward direction (Klein, Addis, & Kahana, 2005). Errors in serial recall are even more informative than contiguity among correct recalls. Applying lag-CRP analyses to recalls following an order error shows a contiguity effect with a clear gradient across lags (Kahana & Caplan, 2002; Solway et al., 2012). Although details of the task such as list length and whether subjects are allowed to skip items appear to impact the exact pattern of errors observed (Farrell, Hurlstone, & Lewandowsky, 2013; Osth & Dennis, 2015), current evidence suggests that serial recall errors are temporally graded (for related evidence from order reconstruction tasks, see Nairne, 1991).

**Finding 30: Compound cuing in recognition.** In Schwartz, Howard, Jing, and Kahana (2005), subjects studied lists of pictures for a recognition test. During test, items that had been studied in adjacent positions in the study list were sometimes probed successively during the test. If temporal associations had formed between items during study, having two successive probes be from adjacent list positions should help recognition because the first item will help cue the second. Such a benefit was observed. Moreover, upon making a high-confidence response for probe  $i$ , subjects' probability of making a high-confidence response to probe  $i + 1$  was a decreasing function of the  $|lag|$  between  $i$  and  $i + 1$  in the study list. That is, if you were highly confident about one probe, then you would be highly confident about the next probe if it came from a nearby position in the

list. This was true even after accounting for autocorrelation in quality of encoding.

Sadeh et al. (2015) reported a similar result in free recall using the remember/know paradigm. They found that transitions from items for which the subject "remembered" the item was on the list showed a stronger contiguity effect than transitions from items which they simply "knew" were on the study list.

Averell, Prince, and Heathcote (2016) replicated the basic Schwartz et al. (2005) finding that matching test order to study order facilitates recognition. Critically, whereas Schwartz et al. (2005) drew their stimuli from a relatively small pool of pictures, Averell et al. (2016) used word lists generated from a large pool of words. The use of a large pool rules out the possibility that temporal proximity is confounded with chance semantic similarities among adjacent list items (Hintzman, 2016).

**Finding 31: Contiguity in paired associates intrusions.** In paired associate learning, subjects have a strong incentive to form associations between items in the same pair but have absolutely no reason to form associations between items in temporally adjacent pairs. In fact, forming such across-pair associations should actually be harmful as it creates a powerful source of interference (Primoff, 1938). Despite these strong incentives to avoid inter-pair associations, analyses of errors in cued recall suggest subjects do indeed form inter-pair associations. Davis, Geller, Rizzuto, and Kahana (2008) examined cases in which subjects incorrectly recalled (intruded) an item from an uncued pair. As in a lag-CRP analysis, they conditionalized the probability of intruding an item from a given lag on the availability of the pair at that lag. These intrusions showed a clear, forward-biased, contiguity effect that extended across many lags (for a similar finding see, Caplan, Glaholt, & McIntosh, 2006).

### Long-range contiguity

In most list learning tasks, items are separated by a few seconds. Outside the laboratory, events can be separated by minutes, hours, or more. Here we review several

## CONTIGUITY IN EPISODIC MEMORY

20

cases where contiguity emerges at these longer time scales.

**Finding 32: Contiguity in prior list intrusions.** When we examine prior-list intrusions (PLI; erroneously recalling a word that was not on the current list but *was* on a prior list), we see they are most likely to come from the most recent list (Murdock, 1974), suggesting temporal proximity influences item's accessibility. Zaromb et al. (2006) directly investigated the influence of temporal associations on the commission of PLIs by creating lists that contained some items that were repeated from earlier lists. Subjects were clearly instructed to recall items from the current list only. They found that PLIs were more likely to follow successful recall of one of the repeated items than recall of a non-repeated item. Moreover, these repetition-evoked PLIs tended to be from the same list as the just-recalled repeated item and from serial positions near to the repeated item's position in the original list. Even clearer evidence of the role of temporal associations in driving intrusions can be seen by examining cases in which subjects make several PLIs in succession: such chains of intrusions showed a clear contiguity effect such that subjects were most likely to transition between PLIs that were temporally contiguous in the original list.

**Finding 33: Across-list contiguity in final free recall.** Across-list temporal associations can also be examined in studies that include a final free recall phase after multiple lists have been studied and recalled. Not surprisingly, final free recall transitions between words studied in the same list show a clear contiguity effect (Howard, Youker, & Venkatadass, 2008; Loaiza & McCabe, 2012; Unsworth, 2008). But contiguity manifests even when subjects *do not* transition between items from the same list: when they make an across-list transition it tends to be to items presented in temporally adjacent lists (Howard et al., 2008; Unsworth, 2008). Across-list contiguity is also apparent in the list-lag of errors when subjects are probed with an item from one list and asked to recall another item from the same list but erroneously recall an item from a different list (Kılıç, Criss, & Howard, 2013). These across-list contiguity effects suggest that subjects are encoding information about temporal distance at the level of lists, even when it is a potential source of

interference.

Figure 5 replicates the final free recall across-list contiguity effect with data from PEERS. This across-list CRP considers only transitions during final free recall that consist of correct recalls from one list to correct recalls of a different list. This analysis controls for the fact that it becomes less likely to transition to a particular list as the number of items that have already been correctly recalled from that list increases. For example, if a subject recalls an item from list #4, it is possible that the next item they recall correctly could be anything that has not already been recalled. If the subject had previously recalled 5 words from list #2, and 10 words from list #9, then there are 11 different items from list #2, and 6 different items from list #9 (assuming 16 item lists) that could be transitioned to. We would increment the denominator for the -2 and +4 possible lags accordingly. The numerator is incremented in the same way; if the next correct recall turns out to be from list #6, and three words had already been recalled from that list, then the +2 lag will be incremented by 13. Following Howard et al. (2008), we also created a surrogate dataset to control for the effects of recency and autocorrelated goodness of encoding. To construct this surrogate data, we took each pair of across-list transitions that were made and then shuffled them so that the same items could not be matched and the pairs must come from different lists. A CRP was then calculated from that shuffled data using the methods described above. This was done 10,000 times for each final free recall session, and then averaged across sessions within a subject, and then across subjects. Although these surrogate data, shown as the solid gray line in Figure 5, do show a small contiguity effect, it cannot account for the large effect seen in the actual data.<sup>2</sup>

---

<sup>2</sup>It has been suggested that the across-list contiguity effect in final free recall may be due to prior-list intrusions and not to temporal associations (Hintzman, 2016). That is, if when originally recalling list  $l$ , subjects intrude an item from list  $l - n$ , they may form new associations between list  $l$  items and list  $l - n$  items. Then, during final free recall, these new intrusion-mediated associations would drive across-list transitions. This is implausible given that intrusions are quite rare and unlike the contiguity effect which extends to lags of 5, intrusions show a very steep recency effect (on average, less than 0.3 of an item per list in the PEERS data, with most coming from no more than 2 lists back; Healey & Kahana, 2016). More to the point, the entire explanation is based on assuming that subjects form associations between temporally contiguous items during recall, despite there being no incentive to form such associations.

**Finding 34: Contiguity outside the lab.** Cortis Mack, Cinel, Davies, Harding, and Ward (2017) tested for contiguity over even longer time scales by using a smart phone application to present items at a rate of 1 word per hour as subjects went about their day. A free recall test following 1 hour after the last item presentation. Even with this very long inter-item interval, there was a robust contiguity effect across three separate experiments and a variety of list lengths. These results provide strong evidence that contiguity is not limited to short time scales.

Perhaps the strongest test of whether contiguity arises at long time scales is to assess whether people encode information about temporal distance as they live their daily lives, incidentally laying down weeks and years of memories. Does recall of autobiographical memories show a contiguity effect? People can reconstruct the order of real world events (e.g., the sequence of events on September 11), and the pattern of order errors shows a clear temporal gradient around the correct position that is remarkably similar to the pattern seen in laboratory list learning tasks (Altmann, 2003). In these studies, subjects were explicitly asked to reconstruct the order of events. Does temporal information influence the recall order when subjects are free to recall autobiographical memories in any order?

Moreton and Ward (2010) asked subjects to free recall events that had occurred in their lives within the last 5 weeks, 5 months, or 5 years. Within each targeted recall-period, subjects showed a contiguity effect, a tendency to make recall transitions between events that were within the same relative retention interval (e.g., upon recalling an event from 3 weeks/months/years ago, they were more likely to transition to recalling another event that occurred 3 weeks/months/years ago than one that had occurred 2 or 4 weeks/months/years ago). A limitation of this study is that it potentially confounds semantic similarity with temporal distance (Hintzman, 2016). For example, events that occur during temporally-proximate periods of your life are more likely to involve similar people and places than events that occur during more temporally-distant periods. Memorable events are also likely to occur in bursts (e.g., the various moments in your

## CONTIGUITY IN EPISODIC MEMORY

23

1  
2  
3  
4 child's first year of life, or the first few months in a new job or city) which can create an  
5 artificial contiguity effect in the same way autocorrelated variation in encoding efficiency  
6 can (see above)—if most events are separated by short lags, short lags will tend to be  
7 overrepresented in the recall sequence.  
8  
9  
10

11  
12 Uitvlugt and Healey (in press) attempted to address these issues by asking people to  
13 recall news stories from one of two time periods: the 2016 presidential election campaign  
14 (Experiment 1) or the first four months of 2018 (Experiment 2). Subjects were asked to  
15 recall events from these time periods, in any order they wanted, by writing a headline to  
16 describe each recalled story. Because these events are public knowledge, not  
17 autobiographical, they can be dated precisely and their semantic similarity measured (in  
18 Experiment 1 by having many crowd-sourced raters judge the similarity of the headlines  
19 involved in each transition and in Experiment 2 by running Latent Semantic Analysis on  
20 the text of published accounts of the events). Even after controlling for the influences of  
21 both the distribution of possible lags and the confound between lag and semantic  
22 similarity, subjects showed a strong bias to transition among events that had appeared in  
23 the news within days of each other.

35  
36

37 Although, to our knowledge, Moreton and Ward (2010) and Uitvlugt and Healey (in  
38 press) are the only studies to examine the contiguity effect in real world memories using  
39 behavioral measures, Nielson, Smith, Sreekumar, Dennis, and Sederberg (2015) examined  
40 contiguity in the neural representations of autobiographical events. They had subjects wear  
41 "lifelogging" cameras and GPS devices for a month and then had them recall specific  
42 events, cued by pictures from the camera, while undergoing MRI scans. For each pair of  
43 events, they computed the similarity between their neural representations and found that  
44 this similarity was robustly correlated with the temporal distance separating the events.  
45 That is, events that occurred in the same day had neural representations that were more  
46 similar to each other than did events that occurred in the same week, which in turn had  
47 more similar neural representations than events that occurred in the same month. This was  
48

true even after controlling for the spatial distance between the events.

### Theoretical Implications

In these final sections we condense the 34 wide-ranging findings reviewed above into three key characteristics of the contiguity effect. In doing so we point to several open questions. We end by asking which cognitive mechanisms are likely to produce these key characteristics.

#### Key Characteristics of Temporal Contiguity

**Automaticity.** We have seen that the temporal contiguity effect is ubiquitous in free recall. It is modulated to varying degrees by many factors, but eliminated by none of them. The effect emerges in the other classic memory paradigms as well (serial recall, recognition, and paired associates learning). It also emerges in errors in free recall, paired associates, and serial recall. It emerges on surprise memory tests. And it emerges outside the lab in the recall of both autobiographical memories and memory for world events. Taken together, this pattern of results suggests that the memory system *automatically* encodes information about temporal proximity, regardless of the details of the current task and even when there is no expectation that temporal information will be helpful on a later memory test. Moreover, the memory system tends to use this information to guide memory search, even when other associative dimensions (like semantic similarity or presentation modality) are available to support recall.

Although the existing data are quite clear on this point, the scope of the existing data is limited. Almost all of the studies reviewed here are word-list learning tasks, and almost all of those use lists of words with minimal semantic structure. Those studies that have added some semantic structure to lists have found contiguity to be present at reduced levels. This raises the question of how important temporal contiguity is when encoding and searching for memories that have rich similarity structures along a variety of dimensions (e.g., semantic, spatial, perceptual, etc.). Some work, such as that showing contiguity in

1  
2  
3 autobiographical memory, suggest that temporal proximity is important when recalling  
4 richer memories, but this literature is in its infancy. An important target for future work is  
5 to explore how different associative dimensions interact and determine whether temporal  
6 proximity enjoys a privileged status in the similarity structure of memory.  
7  
8  
9  
10

11  
12 **Time Scale Similarity.** In most free recall studies, items are separated by  
13 fractions of a second. In CDFR items are separated by multiple seconds. In studies of final  
14 free recall, lists are separated by minutes. In the Cortis Mack et al. (2017) study presenting  
15 items on subjects' phones, items were separated hours. In the real world studies of  
16 Moreton and Ward (2010) and Uitvlugt and Healey (in press) events were separated by  
17 days, weeks, months, and even years. Robust temporal contiguity effects have been  
18 documented at all of these time scales. This suggests that the temporal contiguity effect,  
19 and the mechanisms that produce it, are at least approximately time scale invariant.  
20  
21  
22  
23  
24  
25  
26  
27  
28

29 Exactly how invariant is the contiguity effect to changes in time scale? The data in  
30 Figure 2L show a somewhat smaller effect in CDFR than in immediate free recall.  
31 Similarly, as noted by Howard, Shankar, Aue, and Criss (2015), the contiguity effect  
32 observed in final free recall is shallower and less asymmetric than that observed in  
33 immediate free recall. Uitvlugt and Healey (in press) also found that contiguity in recall of  
34 news events was close to symmetric and that magnitude of the effect was different for  
35 events spread out over two years versus four months. These observations suggest that the  
36 effect may not be precisely time scale invariant. But comparing lag-CRPs across task  
37 conditions, studies, and stimuli type is complicated by variations in overall recall level—as  
38 discussed in the section on autocorrelation in goodness of encoding, differences in the shape  
39 of the CRP could be due to differences in item availability rather than the strength of  
40 temporal associations. To our knowledge, there has been no systematic analysis of the  
41 contiguity effect across multiple time scales that controls for item availability. Such an  
42 analysis will be needed to adjudicate between models that are truly time scale invariant  
43 (e.g., Howard et al., 2015; Shankar & Howard, 2012) and those that are merely  
44  
45  
46

58  
59  
60

1  
2  
3 approximately invariant (e.g., Farrell, 2012; Lohnas, Polyn, & Kahana, 2015).

4  
5  
6 **Forward Asymmetry.** The contiguity effect in free recall has a pronounced  
7 forward asymmetry. This asymmetry is highly robust—all of the effects in Figure 2 show  
8 it. Any theory of episodic memory encoding and search must be able to account for this  
9 regularity.  
10  
11  
12  
13

14 But is forward asymmetry a necessary consequence of the mechanisms that produce  
15 contiguity? The data are less clear on this point. In final free recall, the across-list  
16 contiguity effect (Figure 5) is not forward-asymmetric (see also Howard et al., 2008).  
17 Forward asymmetry was found by Cortis Mack et al. (2017) when items were separated by  
18 hours, but was not found consistently by (Uitvlugt & Healey, in press) when events were  
19 separated by days and weeks. This might suggest that time scale has different effects on the  
20 magnitude of the contiguity effect versus the magnitude of the asymmetry effect (consistent  
21 with the prediction of some models, Howard, 2004). Thus a better understanding of the  
22 factors that influence asymmetry is an important target for future work.

### 35 **Contiguity Generating Mechanisms**

36  
37  
38 We will consider six mechanisms commonly found in contemporary models of episodic  
39 recall: associative chaining, short-term memory, positional coding, chunking, contextual  
40 dynamics, and control processes. The mechanisms are not all mutually exclusive. Indeed,  
41 many models include several of them, such as contextual dynamics and short-term memory  
42 (e.g., Davelaar, Goshen-Gottstein, Ashkenazi, Haarmann, & Usher, 2005; Lehman &  
43 Malmberg, 2013) or contextual dynamics and chunking (Farrell, 2012). Nonetheless, it is  
44 useful to ask which of the mechanisms provide the most comprehensive and parsimonious  
45 account of the available data. Therefore, for each mechanism we will describe how it can  
46 facilitate the encoding of temporal proximity and ask whether it can account for the three  
47 key characteristics of contiguity we outlined above. We track the results in Table 2.  
48  
49  
50  
51  
52

54  
55  
56  
57  
58  
59  
60

1  
2  
3  
4       **Associative Chaining.** Associative chaining models assume that new  
5 associations form directly between successive items during study (Humphreys, Bain, &  
6 Pike, 1989; Lewandowsky & Murdock, 1989; Solway et al., 2012). That is, chaining directly  
7 encodes temporal proximity by forming associations between temporally adjacent items.  
8 Insofar as these models hold chaining to be a fundamental property of the memory system,  
9 they naturally account for the apparent automaticity of the contiguity effect. But if the  
10 chain links only adjacent items (i.e., nearest neighbor chaining Lewandowsky & Murdock,  
11 1989; Metcalfe & Murdock, 1981), the result would be a very steep, and symmetric,  
12 contiguity effect such that recalling item  $i$  would almost always be followed by recalling  
13 either  $i + 1$  or  $i - 1$ . Elaborated versions of chaining may be able to produce a smooth  
14 lag-CRP by allowing associations between non-adjacent items (Solway et al., 2012) or by  
15 using blurred representations as recall cues (so they provided evidence for items at multiple  
16 lags; e.g. Lewandowsky & Murdock, 1989). Time scale similarity and forward asymmetry  
17 pose a greater challenge for chaining. Time scale similarity is a problem because chaining  
18 offers no explanation of how direct links could form between lists separated by minutes in  
19 final free recall or life events separated by weeks in autobiographical memory—one would  
20 have to postulate multiple chains, each with a different timescale. Asymmetry is a problem  
21 because most chaining models, especially those that use correlation to form associations  
22 and convolution to retrieve items (e.g., Lewandowsky & Murdock, 1989) embody a holistic  
23 (Gestalt) view of associations whereby the forward and backward associations are  
24 symmetric (Caplan, Rehani, & Andrews, 2014; Kahana, 2002), without ad hoc  
25 modification it would be difficult for such a model to produce a forward asymmetric chain.  
26

39  
40  
41  
42  
43  
44  
45  
46  
47

48       **Short-Term Memory.** Many models assume that when items spend time  
49 together in short-term memory (or working memory), new long-term associations form  
50 between them (Cowan, Donnell, & Saults, 2013), with the strength of the association being  
51 a function of how much time they spend together (Raaijmakers & Shiffrin, 1981). If items  
52 presented close together in a list tend to spend more time co-occupying short-term memory  
53

## CONTIGUITY IN EPISODIC MEMORY

28

1  
2  
3  
4 than items presented further apart in the list (e.g., Phillips, Shiffrin, & Atkinson, 1967), a  
5  
6 contiguity effect will naturally be produced (Kahana, 1996). Moreover, on the assumption  
7  
8 that passing through short-term memory is the only way for items to get encoded in  
9  
10 long-term memory (Atkinson & Shiffrin, 1968), contiguity in immediate recall would be  
11  
12 automatic and ubiquitous. But short-term memory can not easily account for contiguity  
13  
14 between events that were separated by several seconds of filled distraction (Howard &  
15  
16 Kahana, 2002a), much less between events separated by hours or days. At shorter time  
17  
18 scales, several dual-store models have been shown to produce a contiguity effect that closely  
19  
20 agrees with the forward-asymmetric shape of the contiguity effect observed in immediate  
21  
22 and delayed free recall (Davelaar et al., 2005; Kahana, 1996; Lehman & Malmberg, 2013).  
23  
24 Thus short-term memory can automatically produce forward-asymmetric contiguity at  
25  
26 short time scales, but additional mechanisms are needed to explain long-range contiguity.  
27

28  
29 One such mechanism could be a reminding process. Reminding refers to the  
30  
31 phenomenon of a new event spontaneously triggering retrieval of an earlier event (e.g.,  
32  
33 Hintzman, 2011; Wahlheim & Jacoby, 2013). To illustrate, imagine if the semantically  
34  
35 related words *dog* and *cat* both appeared in a list separated by some lag. Presentation of  
36  
37 *dog* could remind the subject that *cat* had been studied earlier, allowing the two to  
38  
39 co-occupy short-term memory and thus form a new episodic link that increases the  
40  
41 probability they will be recalled together. In situations where the semantic similarity  
42  
43 between two events tends to be positively correlated with the temporal lag separating those  
44  
45 events, reminding could contribute to a contiguity effect even at long time scales. Uitvlugt  
46  
47 and Healey (in press) found evidence that just such a positive correlation between  
48  
49 similarity and lag exists in real-world news stories and contributes to, but does not fully  
50  
51 explain, the contiguity effect. A reminding account has more difficulty, however, with the  
52  
53 long-range contiguity effects observed in continual distractor free recall and final free where  
54  
55 lists are randomly generated such that, across subjects, there should be no correlation  
56  
57 between similarity and lag.  
58  
59  
60

## CONTIGUITY IN EPISODIC MEMORY

29

1  
2  
3  
4       **Positional Coding.** Positional coding models (e.g., Burgess & Hitch, 2006;  
5  
6 Farrell & Lewandowsky, 2002; Lewandowsky & Farrell, 2000; Oberauer, Lewandowsky,  
7  
8 Farrell, Jarrold, & Greaves, 2012) assume that each list item becomes associated with a  
9  
10 representation that codes the item's position in the input sequence and that these codes  
11  
12 can be used as cues during memory search (for a review see, Caplan, 2015). These position  
13  
14 codes can be explicit representations of list position (Farrell & Lewandowsky, 2002, e.g.,)  
15  
16 or they can be representations of temporal distance from the present moment  
17  
18 (G. D. A. Brown, Neath, & Chater, 2007). If nearby positional codes are similar and thus  
19  
20 confusable (G. D. A. Brown et al., 2007; Farrell & Lewandowsky, 2002; Oberauer et al.,  
21  
22 2012), cuing with positional code  $i$  will activate not just the item from position  $i$  but also  
23  
24 items associated with other positions in a decreasing function of  $|i + lag|$ , producing a  
25  
26 contiguity effect. Provided that events are automatically associated with position codes  
27  
28 whenever episodic memories are formed, even incidentally, positional coding could account  
29  
30 for the automaticity of the contiguity effect. Time scale similarity is also a natural  
31  
32 prediction of models in which the psychological distance between the present moment and  
33  
34 temporal markers is logarithmically compressed (G. D. A. Brown et al., 2007). With the  
35  
36 reasonable added assumption that items occupy a temporally extended region of the time  
37  
38 line (rather than a single point), these time scale similar models would also predict forward  
39  
40 asymmetry (G. D. Brown, Chater, & Neath, 2008).

41  
42       **Chunking.** Chunks, or groups, can be formed by associating each item with a  
43  
44 superordinate representation (e.g., Anderson & Matessa, 1997; Farrell, 2012). A recent  
45  
46 implementation of chunking (Farrell, 2012) includes two key mechanisms that produce  
47  
48 contiguity. First, items separated by small lags in the study list are more likely to be in the  
49  
50 same group than items separated by large lags, thus contiguity will naturally arise by  
51  
52 recalling items within a group before moving on to another group. Second, the model  
53  
54 incorporates a positional coding mechanism such that each item is associated with a  
55  
56 within-group positional code, and these codes are similar for temporally proximate  
57  
58  
59  
60

positions. Therefore, the model generates contiguity for much the same reason a positional coding model does: cuing with positional code  $i$  will activate item  $i$  but also the other items in the group as a decreasing function of their lag from item  $i$ . By itself, chunking would not predict time scale similarity. But the Farrell (2012) model posits a hierarchy of chunks (e.g., items are grouped into list, and within lists into chunks), thus the model could conceivably produce contiguity at a long time scales by adding levels to this hierarchy with increasingly coarse time scales (e.g., day-level chunks, week-level chunks, etc.). Moreover, because items within a cluster are recalled by cuing with position markers in forward serial order, the model also produces a forward asymmetry.

**Contextual Dynamics.** Many models assume that new events become associated with the current state of an internal context representation that continually drifts through a high-dimensional space, with the accessibility of a particular memory depending on its association with the current state of context (Bower, 1967; Estes, 1955; McGeoch, 1932; Mensink & Raaijmakers, 1988; Murdock, 1997; Tulving, 1972; Underwood, 1945). Under *retrieved context* models (for the most recent implementations see, Howard et al., 2015; Lohnas et al., 2015), context drift is not random, but is driven by the cognitive representations activated by newly experienced events (e.g., studying, or recalling, a list item). Because of contextual drift, items that were presented near together in time will be associated with more similar states of context than will items presented farther apart in time. Thus, searching memory by using the context associated with the just-retrieved item as a cue automatically produces a contiguity effect. These models also naturally predict time scale similarity because they use a competitive retrieval rule that is sensitive to the *relative* similarity of contextual states (i.e., states of context separated by 1 second are more similar than states separated by 2 seconds, but states of context separated by 1 min are also more similar than states separated by 2 min). But to show time scale similarity at scales ranging from seconds to weeks (or longer) these models must be extended to include multiple context representations that drift at different rates (Howard et al., 2015).

1  
2  
3 Retrieved context models naturally predict asymmetry because each new item adds its  
4 cognitive representation to context which then becomes associated with items presented  
5 after (but not before) it. Thus during retrieval, the context state of a just-recalled item is a  
6 better cue for items at positive lags than for items at negative lags (Howard & Kahana,  
7 2002a).

8  
9  
10  
11  
12  
13  
14 **Control Processes.** Control processes (Atkinson & Shiffrin, 1968; Lehman &  
15 Malmberg, 2013) allow us implement various ad hoc encoding and retrieval strategies to  
16 meet the demands of particular tasks (e.g., Delaney & Knowles, 2005; Unsworth, 2016).  
17 Some of these strategies could produce a contiguity effect (Hintzman, 2016). For example,  
18 subjects may link successive list items together to tell a story (Delaney & Knowles, 2005),  
19 or they might employ the method of loci (Bouffard et al., 2018), linking items to a  
20 pre-memorized sequence of locations. These strategies entail attending to the order of  
21 presentation and recapitulating it during recall: both would produce a contiguity effect.  
22 Such strategies almost certainly contribute to the contiguity effect observed in standard  
23 free recall tasks, but it is difficult to see how they can provide a parsimonious account of  
24 the apparent automaticity of the effect. Particularly problematic are cases where subjects  
25 have no reason to engage in a contiguity-generating strategy, such as when contiguity is  
26 observed under incidental encoding, in across-pair errors in paired associate learning, in  
27 across-list transitions in final free recall, and in recall of real-world events. Similarly, it is  
28 unclear how strategic control processes can provide a unified account of contiguity across  
29 time scales. Certain strategies could produce a forward asymmetry (the method of loci, for  
30 example) under the limited range of situations where subjects would choose to employ the  
31 strategy.

40  
41  
42  
43  
44  
45  
46  
47  
48  
49  
50  
51 Reviewing Table 2, we see that several of the mechanisms are unlikely to provide a  
52 comprehensive account of the contiguity effect. Chaining, short-term memory, and  
53 strategic control processes are all unable to account for the time scale similarity of the  
54 effect. Chaining and strategic control processes also do not provide a natural account of  
55  
56  
57  
58  
59  
60

1  
2  
3 forward asymmetry. And strategic control processes cannot account for the ubiquity and  
4 seeming automaticity of the contiguity effect. This does not mean that these processes  
5 never contribute to the contiguity effect in particular studies. But it does mean that a  
6 comprehensive model of the contiguity effect must include additional mechanisms. The  
7 remaining three mechanisms are good candidates. Contextual dynamics and the most  
8 sophisticated implementations of positional coding and hierarchical chunking are all  
9 consistent with the three key characteristics of the contiguity effect given reasonable  
10 assumptions. It is possible that a complete model of the contiguity effect will have to  
11 include all three . But this would be an unparsimonious conclusion at this point. Instead,  
12 we suggest that the 34 effects reviewed here can serve as a set of benchmarks for modeling  
13 work aimed at determining whether any of these mechanisms can provide a quantitatively  
14 precise account of the available data.

### 29 **Summary and Final Remarks**

30  
31  
32 Memory search unfolds as a series of retrievals, with one retrieved memory triggering  
33 retrieval of another. The temporal distance between events helps drive this chain of  
34 retrievals: upon successfully retrieving one event, subjects have a strong bias to next  
35 retrieve an event that occurred close in time to the just-recalled event. Here, we have  
36 examined how this contiguity effect is influenced by a range of variables. We found that  
37 although many factors influence the magnitude of the contiguity effect, few, if any,  
38 eliminate it.  
39  
40  
41  
42  
43  
44  
45

46 We saw that the contiguity effect is present in essentially all individuals and its  
47 magnitude is positively correlated with both recall success and general intellectual ability.  
48 Within individuals, a robust contiguity effect is observed on their very first free recall trial  
49 and remains even after they gain weeks of experience with the task. Moreover, the effect  
50 cannot be explained by within-individual variation in goodness of encoding. Contiguity is  
51 robust to many different parameters of the free recall task, including list length,  
52

## CONTIGUITY IN EPISODIC MEMORY

33

1  
2  
3 presentation rate, modality of presentation, modality of recall responses, retention interval,  
4 inter-item delay, encoding task, and the semantic associations among list items.  
5  
6

7 The contiguity effect also generalizes beyond accurate retrievals in free recall and is  
8 observed even in situations where it would be difficult or counterproductive to deliberately  
9 encode temporal distance. These include across-list transitions in final free recall, intrusion  
10 errors in free recall, order errors in serial recall, across-pair intrusions in paired associate  
11 learning, and compound-cuing in recognition. Finally, we discussed several studies that  
12 showed contiguity effects in the recall of real-life memories formed outside the lab.  
13  
14  
15  
16  
17  
18

19 We have shown that a successful model of contiguity effects in episodic memory must  
20 encode information about temporal distance at multiple time scales. The mechanisms that  
21 encode this information about temporal distance should generalize across tasks, encoding  
22 manipulations, and materials, suggesting a degree of automaticity. Among the models we  
23 have reviewed, the data appear most consistent with either retrieved-context models, some  
24 positional coding and hierarchical-clustering models or hybrid models that combine these  
25 mechanisms.

## CONTIGUITY IN EPISODIC MEMORY

48

Table 2

*Which mechanisms can account for the key characteristics of the temporal contiguity effect?*

Mechanism	Automaticity	Time Scale	Similarity	Forward Asymmetry
Associative Chaining	✓		×	×
Short-Term Memory	✓		×	✓
Positional Coding	✓		✓	⊖
Chunking	✓		⊖	✓
Contextual Dynamics	✓		⊖	✓
Control Processes	×		×	×

✓ = The mechanism provides a natural account. ⊖ = The mechanism can provide an account given reasonable additional assumptions. × = The model cannot provide an account even with reasonable modifications.

For Review Only

## CONTIGUITY IN EPISODIC MEMORY

49

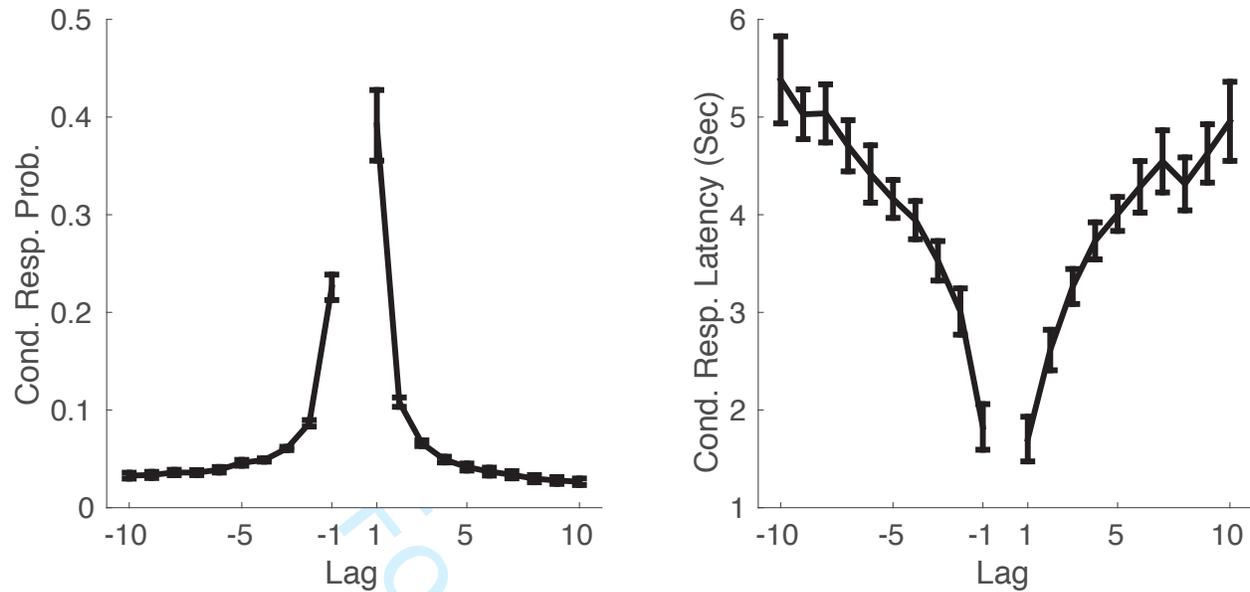

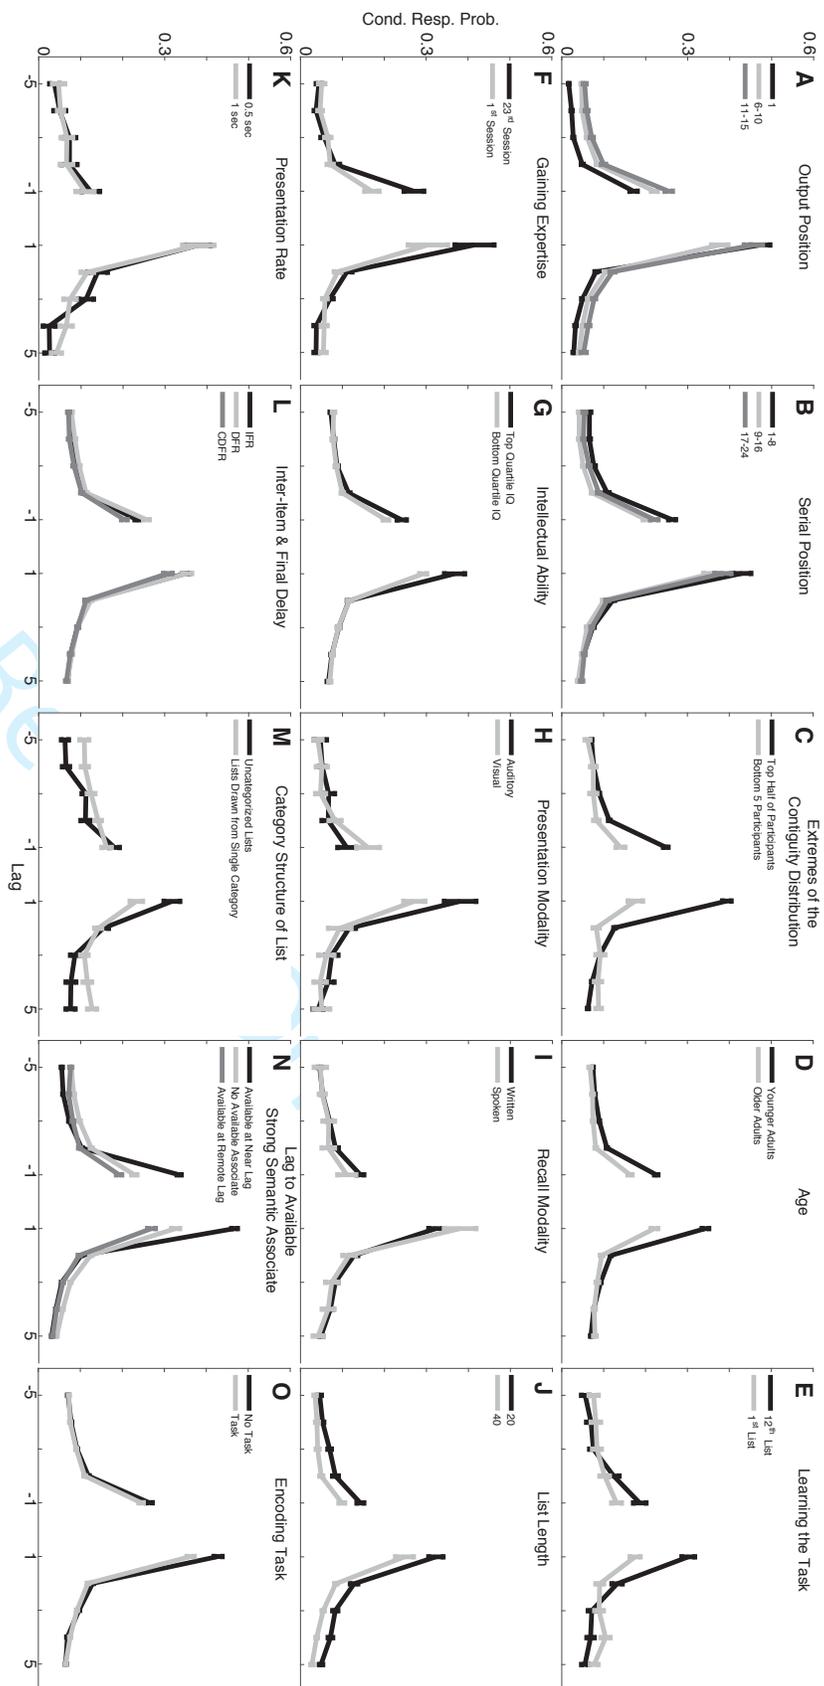

Figure 1. The contiguity effect: Recall of one event triggers recall of other events that occurred near in time. (A) The *conditional-response probability* as a function of lag (lag-CRP) shows the probability of recalling an item from serial position  $i + lag$  immediately following recall of an item from serial position  $i$ . (B) The *conditional response latency* as a function of lag (lag-CRL) shows the mean inter-response time between successive recalls of items from serial positions  $i$  and  $i + lag$ . Data are from Experiment 4 of the Penn Electrophysiology of Encoding and Retrieval Study (PEERS). Subjects studied lists of 24 words for delayed free recall. Error bars are 95% within-subject confidence intervals (Loftus & Masson, 1994).

## CONTIGUITY IN EPISODIC MEMORY

*Figure 2.* Many variables influence the contiguity effect. (A) Output position 1 vs. output positions 6–10 and 11–15 from PEERS Experiment 4. (B) Transitions originating from serial positions 1–8, 9–16, and 17–24 from PEERS Experiment 4. (C) Subjects with temporal factor scores in the top half of the distribution vs. subjects with the 5 lowest scores across both age groups in PEERS Experiment 1. (D) Younger vs. older adults in PEERS Experiment 1. (E) First vs. last (12<sup>th</sup>) list in the screening session of PEERS. (F) Naïve subjects' first vs. 23<sup>rd</sup> session in PEERS Experiment 4. (G) Top vs. bottom quartile of the younger adult IQ distribution in PEERS Experiment 1. (H) Auditory vs. visual presentation in the 1 sec presentation rate condition in Experiment 1 of Murdock and Walker (1969). (I) Written vs. spoken recall in Murdock and Walker (1969) and Murdock (1962) respectively (20-item lists presented auditorily for 1 sec/item in both cases). (J) List length 20 vs. 40 in Murdock (1962, 1 sec presentation rate). (K) Presentation rates of 0.5 sec vs. 1 sec in Experiment 1 of Murdock and Walker (1969). (L) Immediate, delayed, and continual distractor recall conditions from PEERS Experiments 1–3. (M) Uncategorized lists vs. lists drawn from a single category in McCluey et al. (2018). (N) Transitions originating from items that had a strong associate ( $WAS\ cos(\theta) > .7$ ) available only at  $lags > 5$  vs. items that had a strong associate available at  $lags \leq 2$  vs. items that had no strong associates available in PEERS Experiments 1–3. (O) Lists with vs. without an encoding task in Immediate free recall lists of PEERS Experiments 1–3.

## CONTIGUITY IN EPISODIC MEMORY

51

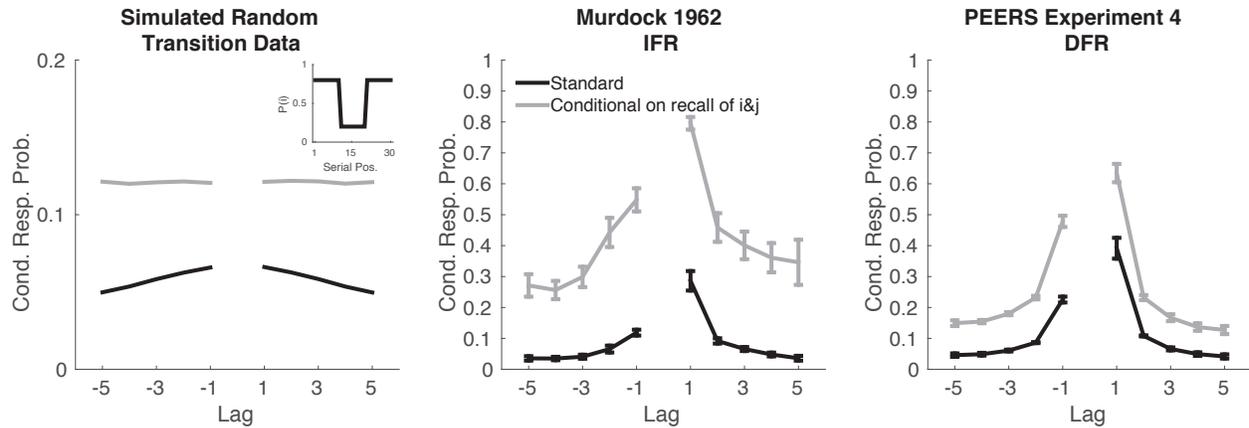

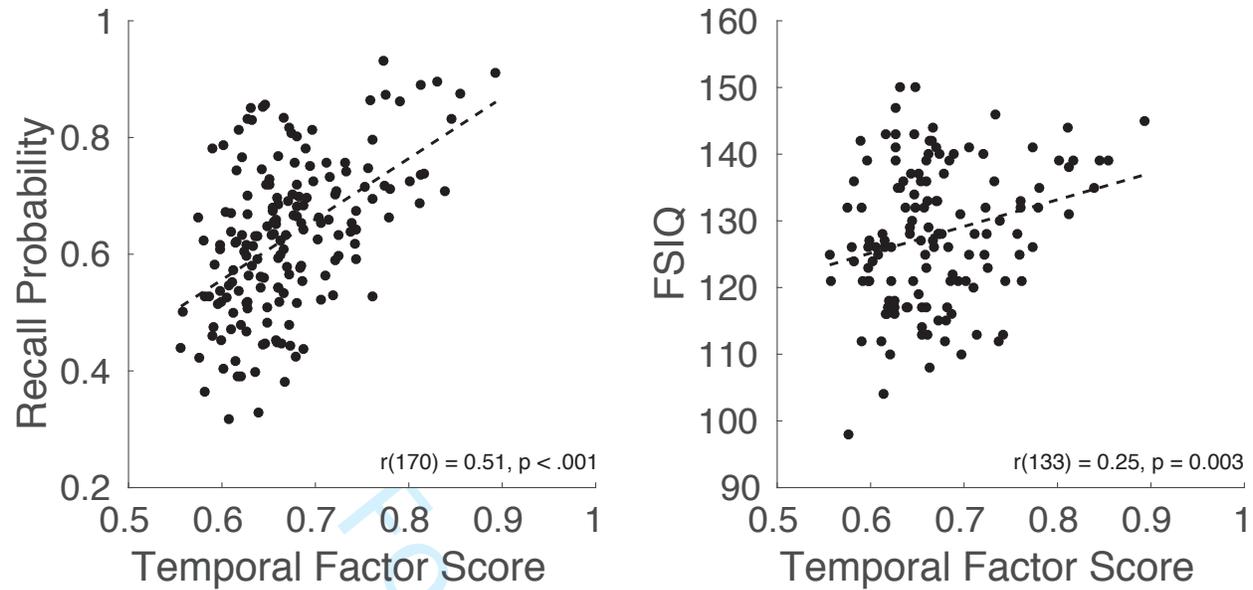

Figure 3. Conditionalizing on availability of both items  $i$  and  $j$  does not eliminate the contiguity effect. (A) A simulated artifactual contiguity effect from a model in which the probability of successful encoding varies by serial positions (see inset) but transitions between items are random with respect to study lag (see Appendix B for details). (B) Immediate recall of 30-item lists from Murdock (1962). (C) Delayed free recall of lists of 24 items in PEERS Experiment 4. Error bars are 95% within-subject confidence intervals (Loftus & Masson, 1994).

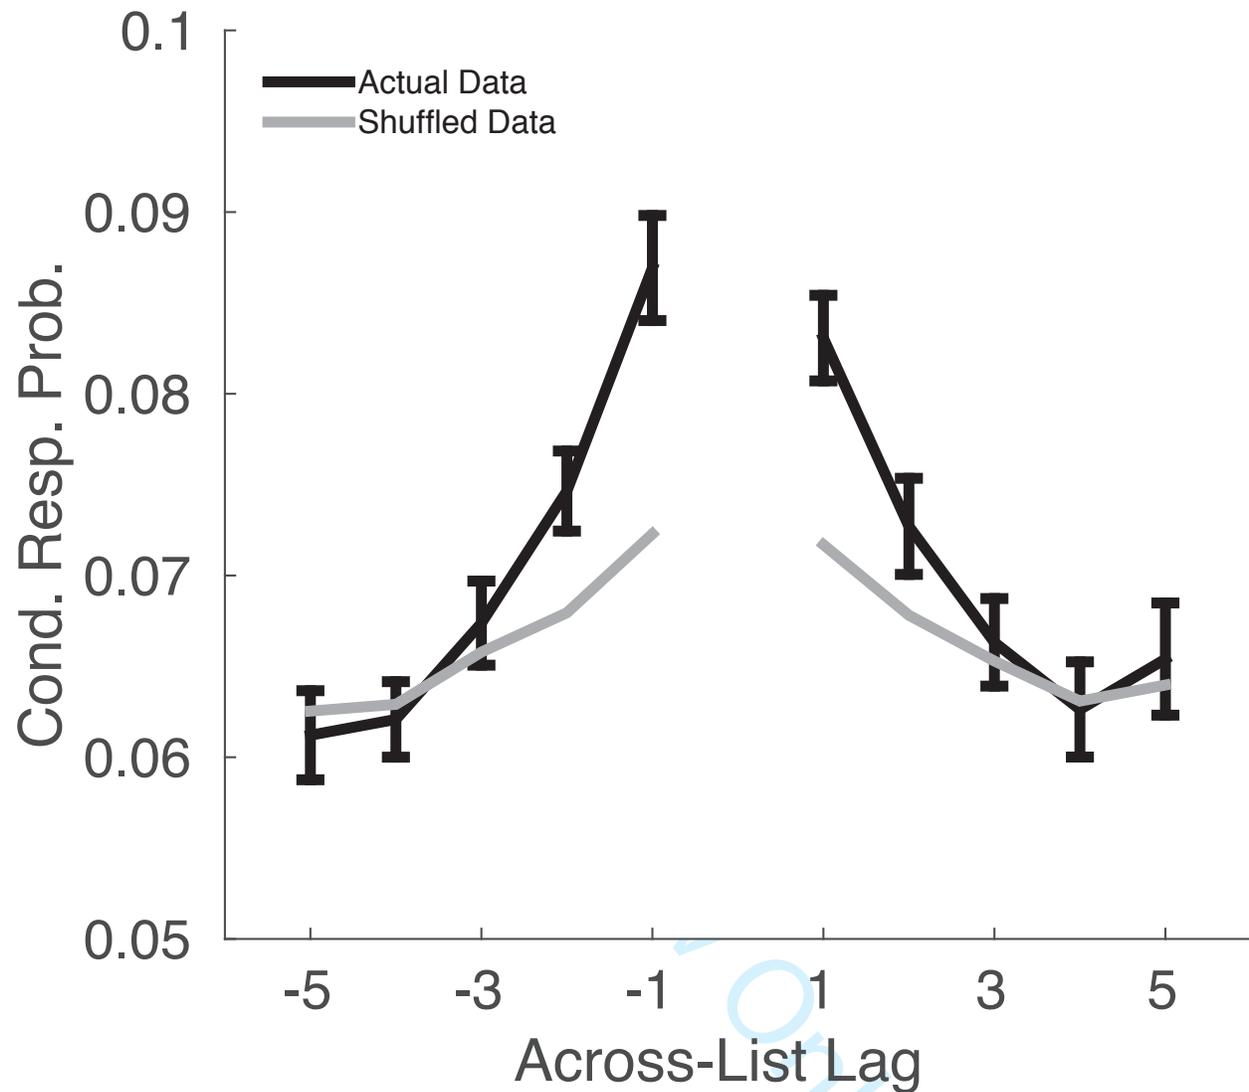

## CONTIGUITY IN EPISODIC MEMORY

52

*Figure 4.* Individual differences in contiguity predict memory performance and IQ (A) The correlation between temporal factor scores and overall recall probability. Temporal factor scores give the average percentile ranking the temporal lag of each actual transition with respect to the lags of all transitions that were possible at that time. (B) The correlation between temporal factor scores and full-scale Wechsler Adult Intelligence Scale IV IQ. Computed using all immediate free recall trials from younger adults in Experiments 1–3 of the Penn Electrophysiology of Encoding and Retrieval Study (PEERS).

## CONTIGUITY IN EPISODIC MEMORY

*Figure 5.* Across-list transitions during final free recall show a contiguity effect. The black curve shows the conditional response probabilities computed from the actual data. The gray curve shows the conditional probability from surrogate data in which the order of recalls are randomly shuffled. The across-list contiguity effect is larger in the actual data than in the surrogate data. Data are from PEERS Experiments 1–3. Error bars are 95% within-subject confidence intervals (Loftus & Masson, 1994).

## Appendix

## Penn Electrophysiology of Encoding and Retrieval Study

The Penn Electrophysiology of Encoding and Retrieval Study (PEERS) aims to assemble a large database on the electrophysiological correlates of memory encoding and retrieval (Healey et al., 2014; Healey & Kahana, 2014, 2016; Lohnas & Kahana, 2013, 2014; Miller et al., 2012). Here, we report data from Experiments 1 and 4. We describe the methods of those experiments in detail (for full details on the design of PEERS, see Healey & Kahana, 2014; Lohnas & Kahana, 2013).

**Subjects**

The present analyses are based on the subjects who had began PEERS as of April 2015. The sample included 466 subjects who completed an introductory session. Of these, a subset consisting of 172 younger adults (age range: 18–30 years) and 38 older adults (age range: 61–85 years) completed all sessions of Experiment 1 (see Healey & Kahana, 2016, for full details on the older adult sample). Of the younger adult sample, 31, the practiced group, also completed at least 12 sessions of Experiment 4. A second subset of 20 younger adults, the naïve group, completed at least 12 sessions of Experiment 4 but had *not* participated in Experiments 1–3. All subjects were right-handed native English speakers. The methods for this study were approved by the University of Pennsylvania Institutional Review Board.

**PEERS Introductory Session**

Prospective subjects completed a introductory session to introduce them to the free recall task and ensure they did not make any excess of eye movements during item presentation epochs (to avoid muscle artifacts making EEG data unusable) and had a probability of recall less than 0.8 (to avoid subject's being at ceiling even before practice). The introductory session consisted of 12 lists of 16 words presented one at a time on a

## CONTIGUITY IN EPISODIC MEMORY

55

1  
2  
3  
4 computer screen for 1600 ms, followed by a jittered (i.e., variable) inter-stimulus interval of  
5  
6 800–1200 ms (uniform distribution).

7  
8 The final word of each list was followed by a distractor period in which subjects  
9  
10 answered math problems of the form  $A + B + C = ?$ , where  $A$ ,  $B$ , and  $C$  were positive,  
11  
12 single-digit integers, though the answer could have been one or two digits. When a math  
13  
14 problem was presented on the screen, the subject typed the sum as quickly as possible.  
15  
16 The task was self-paced and lasted a minimum of 20 s although if the subject was working  
17  
18 on a problem when the time expired, they were allowed to complete that problem.

60  
Subjects performed a free recall experiment consisting of 1 practice session and 6  
subsequent experimental sessions. Each session consisted of 16 lists in which 16 words were  
presented one at a time on a computer screen. Each study list was followed by an  
immediate free recall test. At the end of each session, there was a recognition test and, for  
a subset of sessions, a final free recall test.

Words were either presented concurrently with a task cue, indicating the judgment  
that the subject should make for that word, or with no encoding task. The two encoding  
tasks were a size judgment (“Will this item fit into a shoebox?”) and an animacy judgment  
 (“Does this word refer to something living or not living?”), and the current task was  
indicated by the color and typeface of the presented item. There were three conditions:  
no-task lists (subjects did not have to perform judgments with the presented items),  
single-task lists (all items were presented with the same task), and task-shift lists (items  
were presented with either task). List and task order were counterbalanced across sessions  
and subjects.

Each word was drawn from a pool of 1638 words. Lists were constructed such that  
varying degrees of semantic relatedness occurred at both adjacent and distant serial  
positions. Semantic relatedness was determined using the Word Association Space (WAS)

## CONTIGUITY IN EPISODIC MEMORY

56

1  
2  
3  
4 model described by Steyvers, Shiffrin, and Nelson (2004). WAS similarity values were used  
5  
6 to group words into four similarity bins (high similarity:  $\cos \theta$  between words  $> 0.7$ ;  
7  
8 medium-high similarity,  $0.4 < \cos \theta < 0.7$ ; medium-low similarity,  $0.14 < \cos \theta < 0.4$ ; low  
9  
10 similarity,  $\cos \theta < 0.14$ ). Two pairs of items from each of the four groups were arranged  
11  
12 such that one pair occurred at adjacent serial positions and the other pair was separated by  
13  
14 at least two other items.

15  
16 For each list, there was a 1500 ms delay before the first word appeared on the screen.  
17  
18 Each item was on the screen for 3000 ms, followed by a jittered (i.e., variable)  
19  
20 inter-stimulus interval of 800–1200 ms (uniform distribution). If the word was associated  
21  
22 with a task, subjects indicated their response via a keypress. After the last item in the list,  
23  
24 there was a jittered delay of 1200–1400 ms, after which a tone sounded, a row of asterisks  
25  
26 appeared, and the subject was given 75 seconds to attempt to recall aloud any of the  
27  
28 just-presented items. If a session was randomly selected for final free recall, following the  
29  
30 immediate free recall test from the last list, subjects were shown an instruction screen for  
31  
32 final free recall, telling them to recall all the items from the preceding lists. After a 5  
33  
34 second delay, a tone sounded and a row of asterisks appeared. subjects had 5 min to recall  
35  
36 any item from the preceding lists. After either final free recall or the last list's immediate  
37  
38 recall test, there was a recognition test, which is not considered here (for full details, see  
39  
40 Healey & Kahana, 2016; Lohnas & Kahana, 2013).

**PEERS Experiment 2**

41  
42  
43  
44  
45  
46  
47 Experiment 2 was identical to Experiment 1 except as described below. Each of the 6  
48  
49 non-practice sessions consisted of 12 study lists of 16 words. Distractor tasks consisted of  
50  
51 answering math problems of the form  $A + B + C = ?$ , where  $A$ ,  $B$ , and  $C$  were positive,  
52  
53 single-digit integers, though the answer could have been one or two digits. When a math  
54  
55 problem was presented on the screen, the subject typed the sum as quickly as possible.  
56  
57 The task was self-paced, such that a subject may have been presented with, but not  
58  
59  
60

## CONTIGUITY IN EPISODIC MEMORY

57

1  
2  
3  
4 responded to, a problem at the end of the distraction interval. Subjects were given a  
5  
6 monetary bonus based on the speed and accuracy of their responses. In the first two trials,  
7  
8 subjects performed free recall with one trial having a distractor period following the last  
9  
10 word presentation for 8 s. For the other of the first two trials, subjects performed an 8 s  
11  
12 distractor period prior to and following each word presentation. In the remaining 10 trials,  
13  
14 subjects performed free recall with 5 possible time durations for the between-item and  
15  
16 end-of-list distractor tasks. As listed here, the first number indicated the between-list  
17  
18 distractor duration and the second number indicated the end-of-list distractor, both in  
19  
20 seconds: 0-0, 0-8, 0-16, 8-8, 16-16. A 0 s distractor refers to the typical, non-filled duration  
21  
22 intervals as described for Experiment 1. Within each session, half of the lists were  
23  
24 randomly chosen to be task-switch lists, and the other half were single-task lists.

25  
26 The first session in this experiment was designed to introduce subjects to the math  
27  
28 task. This session was identical to the experimental sessions except as described below.  
29  
30 This session contained 14 lists, the first 4 of which were 2 lists of 8-8 and 2 lists of 0-8, with  
31  
32 the order randomly chosen. These lists were all single-task lists, two each of each judgment  
33  
34 type randomly chosen. The remaining 10 lists had distractor tasks as in the experimental  
35  
36 sessions. All of these lists were single-task lists, with half randomly chosen to be of one  
37  
38 task. This session always contained a final free recall period.

### 41 PEERS Experiment 3

42  
43  
44 Experiment 3 used the externalized recall (ER) procedure (Kahana, Dolan, Sauder, &  
45  
46 Wingfield, 2005; Unsworth & Brewer, 2010; Unsworth, Brewer, & Spillers, 2009; Zaromb et  
47  
48 al., 2006) to obtain more complete information on subjects' tendency to commit intrusions  
49  
50 during recall and on their ability to distinguish between intrusions and correct responses.  
51  
52 In Experiment 3, 96 subjects were given externalized recall instructions and the remaining  
53  
54 subjects were given standard free recall instructions.

55  
56 In the ER procedure, after subjects had become familiar with the standard free recall  
57  
58  
59  
60

## CONTIGUITY IN EPISODIC MEMORY

58

1  
2  
3  
4 instructions, we asked them to say out loud all words that came to mind at the time of  
5  
6 test, even if they thought those words did not occur in the most recent list, which they are  
7  
8 explicitly attempting to recall. To separately examine the internal censoring process during  
9  
10 recall, we asked subjects to indicate when they have recalled an item they believe was not  
11  
12 on the most recent list by pressing the spacebar immediately following recall of that item.

13  
14 The ER procedure was introduced in a preliminary session which began identically to  
15  
16 Experiment 1. After the third list, instructions appeared on the computer screen indicating  
17  
18 that subjects should additionally say aloud every time a specific, salient word came to  
19  
20 mind while performing free recall. Subjects were also instructed to press the spacebar  
21  
22 immediately following recall of an intrusion or repetition. An experimenter sat in with the  
23  
24 subject during this session to ensure that the subject understood these instructions.  
25  
26 Following this preliminary session, subjects performed five experimental sessions with  
27  
28 methods identical to Experiment 1 except that subjects were given ER instructions at the  
29  
30 beginning of each free recall session. Three out of the six (one practice and five  
31  
32 experimental) sessions were randomly chosen to have final free recall, and each of the final  
33  
34 free recall periods also began with the ER instruction.

#### 35 36 37 **PEERS Experiment 4**

38  
39  
40  
41 Subjects performed a delayed free recall experiment consisting of 24 experimental  
42  
43 sessions. Each session consisted of 24 lists of 24 words that were presented one at a time on  
44  
45 a computer screen. Each study list was followed by a 24 s distractor-filled delay before a  
46  
47 free recall test.

48  
49 Each session requires  $24 \times 24 = 576$  words. For each subject, a unique word pool of  
50  
51 576 word was drawn from the larger 1638-word pool used in Experiment 1. This same  
52  
53 576-word pool was used to generate the lists for each session 1–23. That is, subjects saw  
54  
55 the same set of words across sessions 1–23, but randomly assigned to different lists in each  
56  
57 session. The 24<sup>th</sup> session introduced some new words, which were drawn from the  
58  
59  
60

## CONTIGUITY IN EPISODIC MEMORY

59

1  
2  
3  
4 remaining words in the larger 1638-word pool. Specifically, the 24<sup>th</sup> session included 8 lists  
5  
6 composed of 8 old/16 new words, 8 lists composed of 12 old/12 new words, and 8 lists  
7  
8 composed of 16 old/8 new words. Within all sessions, words were randomly assigned to  
9  
10 lists with the following constraints: Lists were constructed such that varying degrees of  
11  
12 semantic relatedness occurred at both adjacent and distant serial positions. WAS similarity  
13  
14 values were used to group words into four similarity bins using the same procedure  
15  
16 described for Experiment 1. Two pairs of items from each of the four groups were arranged  
17  
18 such that one pair occurred at adjacent serial positions and the other pair was separated by  
19  
20 at least two other items.  
21  
22  
23  
24  
25  
26

27 For all lists, there was a 1500 ms delay before the first stimuli appeared on the screen.  
28  
29 For a random half of the lists in each session (excluding list 1), subjects completed a  
30  
31 pre-list distractor task for 24 s before presentation of the first word, with a 800–1200 ms  
32  
33 (uniform distribution) jittered delay between the last distractor problem and the  
34  
35 presentation of the first list word. Each word was on the screen for 1600 ms, followed by a  
36  
37 jittered (i.e., variable) inter-stimulus interval of 800–1200 ms (uniform distribution).  
38  
39 Following the presentation of the last word in each list, subjects performed a distractor  
40  
41 task for 24 s. Both the pre-list and post-list distractor task consisted of answering math  
42  
43 problems of the form  $A + B + C = ?$ , where  $A$ ,  $B$ , and  $C$  were positive, single-digit integers,  
44  
45 though the answer could have been one or two digits. When a math problem was presented  
46  
47 on the screen, the subject typed the sum as quickly as possible. The task was self-paced,  
48  
49 such that a subject may have been presented with, but not responded to, a problem at the  
50  
51 end of the distraction interval. Subjects were given a monetary bonus based on the speed  
52  
53 and accuracy of their responses. After the post-list distractor task, there was a jittered  
54  
55 delay of 1200–1400 ms, after which a tone sounded, a row of asterisks appeared, and the  
56  
57 subject was given 75 s to attempt to recall aloud any of the just-presented items.  
58  
59  
60

### Intelligence Testing

The Wechsler Adult Intelligence Scale (WAIS) IV (Wechsler, 2008) was administered to 135 of the younger adults who completed Experiment 1. WAIS testing was conducted by a trained clinical psychologist in one-on-one sessions after completing all free recall sessions. We omitted the working memory index of the WAIS as we were concerned that subjects' extensive practice with free recall would artificially inflate their scores.

## CONTIGUITY IN EPISODIC MEMORY

2

## Supplemental Materials for Contiguity in Episodic Memory

The lag-CRP analyses presented in the figures in the main text were conducted using the standard algorithm for computing lag-CRPs. In computing the number of times transitions of various lags were possible, this algorithm assumes any transition to an as yet unrecalled list item was possible. As pointed out by Hintzman (2016), this assumption introduces a confound with variations in recall probability across items (e.g., the serial position effect makes transitions to primacy and recency items more likely). See the main text for a more detailed discussion of this issue. To control for such variations in item availability, we can consider transitions to a given item as possible only if that item was successfully recalled *at some point in the recall sequence*. See the main text for full details on this adjustment.

Figure 3 in main text shows this adjustment applied to the data from Murdock (1962) and PEERS Experiment 4, but all other figures in the main text show lag-CRPs computed in the standard way, without the adjustment. Here, we present alternative versions of key figures using the availability adjustment.

Although the availability adjustment provides an important demonstration that autocorrelation in goodness of encoding does not account for the contiguity effect, we argue against making the adjustment standard practice when computing lag-CRPs. The assumption that only items that are actually recalled are available is, of course, unrealistic (Tulving & Pearlstone, 1966). Ignoring many transitions that were indeed possible is likely to reduce the reliability of the denominator in the CRP computation, artificially increasing variance (compare the error bars between the figures with and without the adjustment).

Moreover, caution should be exercised when making comparisons between conditions, especially when the conditions differ in overall recall level. The availability adjustment changes the scale of the effect by making the denominator of the lag-CRP calculation negatively correlated with the number of items recalled. As a consequence, the curves of conditions with lower recall probabilities (e.g., older adults) will be raised relative to curves

## CONTIGUITY IN EPISODIC MEMORY

3

1  
2  
3  
4 of conditions with higher recall probabilities (e.g., younger adults), potentially disguising  
5 the fact that the contiguity effect is shallower in one condition.  
6

7  
8 In practice, a better approach may be to use a reshuffling procedure to estimate the  
9 size of the contiguity effect expected by chance. See Figure 7 of the main text for an  
10 example of this approach.  
11

12  
13 **Main text Figure 1.** An adjusted version of Figure 1 from the main text is shown  
14 in Figure 3 in the main text.  
15

16  
17 **Main text Figure 2.** An adjusted version of Figure 2 is shown in Figure S1.  
18 Again, caution must be exercised when comparing conditions because the adjustment  
19 places conditions with different recall levels on different scales. For example, in Figure S1A  
20 the CRP for  $lag + 1$  is the same for participants in both extremes of the contiguity  
21 distribution, even though the contiguity effect (i.e., the ratio of CRPs for near lags versus  
22 far lags) is much smaller for those in the lower distribution.

## CONTIGUITY IN EPISODIC MEMORY

*Figure S1.* A version of Figure 2 from the main text produced using the availability adjustment (i.e., recomputing the lag-CRP conditional on recall of both item  $i$  and item  $j$ ). (A) Output position 1 vs. output positions 6–10 and 11–15 from PEERS Experiment 4. (B) Transitions originating from serial positions 1–8, 9–16, and 17–24 from PEERS Experiment 4. (C) Subjects with temporal factor scores in the top half of the distribution vs. subjects with the 5 lowest scores across both age groups in PEERS Experiment 1. (D) Younger vs. older adults in PEERS Experiment 1. (E) First vs. last (12<sup>th</sup>) list in the screening session of PEERS. (F) Naïve subjects' first vs. 23<sup>th</sup> session in PEERS Experiment 4. (G) Top vs. bottom quartile of the younger adult IQ distribution in PEERS Experiment 1. (H) Auditory vs. visual presentation in the 1 sec presentation rate condition in Experiment 1 of Murdock and Walker (1969). (I) Written vs. spoken recall in Murdock and Walker (1969) and Murdock (1962) respectively (20-item lists presented auditorily for 1 sec/item in both cases). (J) List length 20 vs. 40 in Murdock (1962, 1 sec presentation rate). (K) Presentation rates of 0.5 sec vs. 1 sec in Experiment 1 of Murdock and Walker (1969). (L) Immediate, delayed, and continual distractor recall conditions from PEERS Experiments 1–3. (M) Uncategorized lists vs. lists drawn from a single category in McCluey, Burke, and Polyn (2018). (N) Transitions originating from items that had a strong associate ( $WAS \cos(\theta) > .7$ ) available only at  $lags > 5$  vs. items that had a strong associate available at  $lags \leq 2$  vs. items that had no strong associates available in PEERS Experiments 1–3. (O) Lists with vs. without an encoding task in Immediate free recall lists of PEERS Experiments 1–3.

## CONTIGUITY IN EPISODIC MEMORY

6

*Figure S2.* A version of Figure 4 from the main text produced using the availability adjustment. Individual differences in contiguity predict memory performance and IQ (A) The correlation between temporal factor scores and overall recall probability. Temporal factor scores give the average percentile ranking the temporal lag of each actual transition with respect to the lags of all transitions that were possible at that time. (B) The correlation between temporal factor scores and full-scale Wechsler Adult Intelligence Scale IV IQ. Computed using all immediate free recall trials from younger adults in Experiments 1–3 of the Penn Electrophysiology of Encoding and Retrieval Study (PEERS). In each session, subjects studied lists of 16 words for immediate free recall.
